Advances in single-cell sequencing and CRISPR technologies have enabled detailed case-control comparisons and experimen-2 tal perturbations at single-cell resolution. However, uncover-3 ing causal relationships in observational genomic data remains 4 challenging due to selection bias and inadequate adjustment for unmeasured confounders, particularly in heterogeneous datasets. 6 To address these challenges, we introduce causarray, a doubly robust causal inference framework for analyzing array-based 8 genomic data at both bulk-cell and single-cell levels. causarray q integrates a generalized confounder adjustment method to ac-10 count for unmeasured confounders and employs semiparamet-11 ric inference with flexible machine learning techniques to en-12 sure robust statistical estimation of treatment effects. Bench-13 marking results show that causarray robustly separates treat-14 ment effects from confounders while preserving biological sig-15 nals across diverse settings. We also apply causarray to two 16 single-cell genomic studies: (1) an in vivo Perturb-seq study of 17 autism risk genes in developing mouse brains and (2) a case-18 control study of Alzheimer's disease using three human brain 19 transcriptomic datasets. In these applications, causarray iden-20 tifies clustered causal effects of multiple autism risk genes and 21 consistent causally affected genes across Alzheimer's disease datasets, ing to potential biases in counterfactual estimation. 22 uncovering biologically relevant pathways directly linked to neu-23 ronal development and synaptic functions that are critical for 24 understanding disease pathology. 25

Keywords: causal inference, confounder adjustment, counterfactual, double 26 robustness, differential expression analysis 27

Introduction 28

The advent of genomic research has transformed our under-29 standing of biological processes and disease mechanisms. Ad-30 vances in single-cell RNA sequencing (scRNA-seq) have driven 31 this rapid progress, offering unprecedented insights into gene 32 expression patterns at the cellular level (1). The high reso-33 lution provided by scRNA-seq data is essential to elucidate 34 cellular heterogeneity and its implications for health and dis-35 ease (2–4). However, fully harnessing the potential of these 36 data requires robust analytical frameworks capable of mov-37 ing beyond association to unravel complex causal relation-38 ships at single-cell resolution (5-7). The fundamental dif-39 ference between association and causation is that associa-40 tion assesses correlations between treatments and outcomes, 41 whereas causal inference aims to quantify the effect of a treat-42 ment on an outcome. A popular framework for causal infer-43 ence is the potential outcomes framework, which estimates 44 what would have happened if a different treatment had been 45

assigned, the counterfactual (7, 8). To understand the inner workings and mechanisms of biological processes and diseases for the purpose of treatments, precision medicine, genomic medicine and more, causal inferences will be required (9, 10).

46

47

48

49

50

One of the primary challenges in leveraging scRNA-seq 51 data for causal inference is its inherent hierarchical organi-52 zation and heterogeneity (6, 7, 11). Cells derived from the 53 same individual are not independent observations; they share 54 biological factors, such as correlated variability and techni-55 cal factors, including batch effects introduced during stor-56 age and sequencing. These dependencies violate the assump-57 tion of independent and identically distributed (i.i.d.) sam-58 ples, complicating statistical analyses and rendering tradi-59 tional methods inadequate for handling heterogeneous data 60 with unwanted variations (12, 13). Furthermore, most ge-61 nomic studies are observational in nature. Unlike randomized 62 controlled trials, observational studies lack complete knowl-63 edge of the disease or treatment assignment mechanism, lead-64 65

CRISPR perturbation experiments, a more recent but rapidly 66 expanding area, offer a new set of challenging analysis sce-67 narios (14–16). For this experimental setting, perturbed cells 68 are contrasted with cells that receive a non-targeting pertur-69 bation. While there is some randomness in the treatment as-70 signment, it is not entirely random: continuous unmeasured 71 confounders such as variability in cell size or differential drug 72 exposure can result in biased causal estimates. Additionally, 73 when such experiments are performed in vivo, the possibility 74 of confounding increases (17), further justifying the need for 75 robust causal inference analysis. 76

Existing methods for causal inference, such as CoCoA-diff 77 (6) and CINEMA-OT (11), rely on simple matching tech-78 niques that assume the causal structure is transferable be-79 tween treatment and control groups. However, this assump-80 tion breaks down when covariate distributions differ signif-81 icantly across groups, leading to biased estimates. More-82 over, even after controlling for observed confounders, un-83 measured confounders can undermine the validity of causal 84 conclusions (18, 19). Other methods like surrogate variable 85 analysis (SVA) (20) and RUV (13) aim to address confound-86 ing and unwanted variation via linear models that assume ad-87 ditive relationships between covariates and outcomes. While 88 effective for certain bulk RNA-seq datasets, these approaches 89 often fail to capture the sparsity, zero inflation, and overdis-90

⁹² ling these challenges requires integrating robust confounder

adjustment with flexible modeling techniques to ensure valid
 causal inference in complex genomic data.

In response to these challenges, we introduce a new frame-95 work for applying causal inference in genomic studies. Our 96 approach leverages generalized factor models tailored to count 97 data to account for unmeasured confounders, ensuring robust 98 adjustment for unmeasured confounders while preserving bi-99 ological signals. It further relies on the potential outcomes 100 framework and employs a doubly robust estimation proce-101 dure, which combines outcome and propensity score models 102 to ensure reliable statistical inference even if one model is 103 misspecified (22, 23). This framework effectively addresses 104 biases introduced by both observed and unobserved confounders. 105 making it particularly well-suited for analyzing complex ge-106 nomic data at both bulk and single-cell levels (Fig. 1a). By 107 integrating advanced statistical and machine learning tech-108 niques with a causal inference framework, our method en-109 ables a range of downstream analyses, including accurate es-110 timation of counterfactual distributions, causal gene detec-111 tion, and conditional treatment effect analysis. This approach 112 not only improves the interpretability and precision of ge-113 nomic analyses but also uncovers critical insights into gene 114 expression dynamics under disease or perturbation conditions, 115 advancing our understanding of underlying biological mech-116 anisms. 117

We demonstrate the effectiveness of causarray through bench-118 marking on several simulated datasets, comparing its per-119 formance with existing single-cell-level perturbation analysis 120 methods and pseudo-bulk-level differential expression (DE) 121 analysis methods. Next, we apply causarray to two single-122 cell genomic studies: a Perturb-seq study investigating autism 123 spectrum disorder/neurodevelopmental disorder (ASD/ND) 124 genes in developing mouse brains and a case-control study of 125 Alzheimer's disease using human brain transcriptomic datasets. 126 For the Alzheimer's disease analysis, we validate our findings 127 across three independent datasets, showcasing the robustness 128 and reproducibility of causarray in identifying causally af-129 fected genes and uncovering biologically meaningful path-130 ways. These applications highlight the potential of causar-131 132 ray to advance our understanding of complex disease mechanisms through rigorous causal inference. 133

134 Results

135 Doubly-robust counterfactual imputation and inference

Our objective is to determine whether a gene is causally af-136 fected by a "treatment" variable after controlling for other 137 technical and biological covariates, which may affect the treat-138 ment and outcome variables. Here, we use the term treatment 139 generally; in the narrow sense, it can mean genetic and/or 140 chemical perturbations (17, 24), such as CRISPR-CAS9, and, 141 more broadly, it can mean the phenotype of a disease (6). We 142 acknowledge that while many differentially expressed genes 143 can be considered a result of disease status, for most late-144 onset disorders, a smaller fraction of genes could have ini-145 tiated disease phenotypes. Our method aims to determine 146

the direct effects of treatments on modulated gene expression outcomes.

147

148

In observational data, the response variable can be con-149 founded by measured and unmeasured biological and tech-150 nical covariates, making it difficult to separate the treatment 151 effect from other unknown covariates. As a consequence, it 152 is challenging to draw causal inferences; even tests of as-153 sociation may lead to an excess of false discoveries and/or 154 low power. Fortunately, the potential outcomes framework 155 (22, 23) formulates general causal problems in a way that al-156 lows for the treatment effect to be separated from the effects 157 of other variables. However, even this framework is chal-158 lenged by unmeasured covariates. Before introducing our 159 method for estimating unmeasured confounders, we first out-160 line the general potential outcomes framework. 161

Consider a study in which Y is the response variable and A is the binary treatment variable for an observation. In the potential outcomes framework, Y(a) is the outcome that we would have observed if we set the treatment to A = a. Naturally, we can only observe one of the two potential outcomes for each observation, so 167

$$Y = \mathbb{1}\{A = 1\}Y(1) + \mathbb{1}\{A = 0\}Y(0),$$
166

In the context of a case-control study of a disease, this would answer the question: What is the expected difference in gene expression if an individual had the disease (case, A = 1) versus if they did not (control, A = 0)?

Doubly robust methods provide a powerful tool for es-173 timating potential outcomes in observational studies where 174 randomization is not possible (22, 23). Specifically, we esti-175 mate two key quantities: (1) $\mu_a(X)$, the mean response of the 176 outcome variable conditional on treatment A = a and covari-177 ates X = x, and (2) $\pi_a(X)$, the propensity score, which is 178 defined as the probability of receiving treatment A = a given 179 covariates X, i.e., $\pi_a(X) = \mathbb{P}(A = a \mid X)$. Using these esti-180 mates, we compute potential outcomes as 181

$$\widehat{Y}(a) = \frac{\mathbb{1}\{A=a\}}{\widehat{\pi}_a(X)}(Y - \widehat{\mu}_a(X)) + \widehat{\mu}_a(X).$$
 182

The doubly robust estimator's name comes from the fact that 183 it provides a consistent estimate as long as *either* the out-184 come model, $\mu_a(X)$, or the propensity score model, $\pi_a(X)$, 185 is correctly specified. Given this estimate, we can easily per-186 form downstream inference tasks such as computing log fold 187 change (LFC) (Methods), and testing for causal effects on 188 gene expressions (Fig. 1a). An advantage of this approach 189 is that counterfactual imputation denoises/balances gene ex-190 pression under two different conditions. Additionally, hav-191 ing access to estimated potential outcomes facilitates down-192 stream analyses such as estimating causal effects conditional 193 on measured confounders like age. 194

A key step in these types of analyses is estimating unmeasured confounders. To adjust for confounding, factor models were popularized in surrogate variable analysis literature and have since been widely adopted in bulk gene expression studies (20). Recently, we extended this approach to singlecell RNA-seq data using generalized linear models that better

Fig. 1. Overview of the proposed causarray method. a, Illustration of the data generation process for pseudo-bulk and single-cell data. b, The gene expression matrix, Y, is linked to the treatment, A, measured covariates, X, and confounding variables, U, via a GLM model. The cell-wise size factor, s, and gene-wise dispersion parameter, ϕ , are estimated from the data, and the unmeasured confounder U is estimated by \widehat{U} through the augmented GCATE method. c, Generalized linear models and flexible machine learning methods including random forest and neural network can be applied for outcome modeling ($\mathbb{E}[Y \mid A = a, X, \widehat{U}] = \widehat{\mu}_a(X, \widehat{U})$) and propensity modeling ($\mathbb{P}(A = a \mid X, U) = \widehat{\pi}_a(X, \widehat{U})$). The estimated outcome and propensity score functions give rise to the estimated potential outcomes for each cell and each gene. d, Downstream analysis includes contrasting the estimated counterfactual distributions, performing causal inference, and estimating the conditional average treatment effects.

accommodate pseudobulk and single-cell outcome variables (18). Using this generalized factor analysis approach, we estimate unmeasured confounders U alongside potential outcomes (Fig. 1b-c), enabling direct estimation of downstream quantities such as LFC (Fig. 1d).

Simulation study demonstrates the advantages of causarray 206

Fig. 2. Benchmarking of causarray against other methods for single-cell differential expression testing on synthetic expression data with unmeasured confounders. a, The analysis pipeline produces a confounder adjustment and a statistic for DE testing. We illustrate two types of criteria used for benchmarking confounder adjustment and DE methods in simulation for bulk simulations (**b**-e) and single-cell simulations (Fig. S1). **b**, Performance comparison of causarray and other methods with a well-specified number of latent factors (r = 4). Bar plots show median ARI and ASW scores for confounder estimation, while box plots display FPR and TPR for biological signal preservation. The top and bottom hinges represent the top and bottom quartiles, and whiskers extend from the hinge to the largest or smallest value no further than 1.5 times the interquartile range from the hinge. The center indicates the median. **c**, Robustness analysis of causarray, RUV-III-NB, and RUV under varying numbers of latent factors (r = 2, 4, 6). Bar plots show ARI and ASW scores for confounder estimation, while box plots display FPR and TPR for DE testing. **d**-e, causarray disentangles the treatment effects and unmeasured confounding effects in the response and confounder spaces. UMAP projection of (**d**) expression data Y colored by the values of treatment A (purple for control A = 0 and yellow for treated A = 1) and unmeasured continuous confounder U; and (**e**) estimated potential outcome under control Y(0) colored by the values of treatment A and continuous confounder U.

variability. Each dataset consists of 100-300 cells, approximately 2,000 genes, 1-2 covariates, and 4 unmeasured confounders.

To benchmark causarray, we compare it with several existing methods designed for differential expression (DE) testing, both with and without confounder adjustment (Fig. 2a).218For methods that do not account for unmeasured confounders,219we include the Wilcoxon rank-sum test and DESeq2 (26). In220the presence of measured covariates, both regress the gene221expression counts with respect to the covariates using the222

Fig. 3. Statistical test results of the effects of CRISPR perturbation on gene expression in excitatory neuron data. a, Number of significant genes detected under all perturbations using three different methods. The detection threshold for significant genes is FDR < 0.1 for all methods. b-c, Heatmaps of GO terms enriched (adjusted P value < 0.05, q < 0.2) in discoveries from causarray and RUV, respectively, where the common GO terms are highlighted in blue. Only the top 20 GO terms that have the most occurrences in all perturbations are displayed. d-e, Barplots of GO terms enriched in discoveries under *Satb2* perturbation from causarray and RUV, respectively.

Poisson or negative binomial generalized linear model, re-223 spectively. The input to the Wilcoxon rank sum test is the de-224 viance residuals. For confounder-adjusted methods, we con-225 sider CoCoA-diff (6), CINEMA-OT (11), CINEMA-OT-W 226 (11), RUV (12), and RUV-III-NB (13), where recommended 227 DE test methods are subsequently applied with estimated con-228 founders. A short summary of each of these benchmarking 229 comparison methods can be found in Methods. 230

To assess the performance of unmeasured confounder adjustment procedures, we use two metrics: adjusted Rand index (ARI) and average silhouette width (ASW). More specifically, we use ARI to quantify the alignment between estimated and true unmeasured confounders and ASW to evaluate cell type separation in the control response space. A higher ARI value indicates better coherence and a higher ASW value reflects better preservation of biological signals after removing confounding effects. Additionally, to assess the performance of DE testing, we use two metrics: false positive rate (FPR) and true positive rate (TPR) (Methods). 238

We first evaluate how sample size and confounding levels influence the performance of DE testing across methods. Among all tested approaches, only causarray, RUV, Wilcoxon, and DESeq2 effectively control FPR across all settings (Fig. 2b and Fig. S1ab). causarray maintains FPR close to the nomi-

Fig. 4. Comparison of DE genes discovered by causarray and RUV on excitatory neurons for Alzheimer's disease. a, The ratio of false discoveries to all 15586 genes of DE test results with permuted disease labels on the ROSMAP-AD dataset. Three methods, causarray with FDX control, causarray with FDR control, and RUV with FDR control, are compared. **b**, The similarity of estimated effect sizes on SEA-AD MTG and PFC datasets. The slope is estimated from linear regression of effect sizes on the PFC dataset against those on the MTG dataset. **c**, DE genes by causarray and RUV over 15586 genes (adjusted *P* value < 0.1). **d**, Venn diagram of associated GO terms from causarray and RUV (adjusted *P* value < 0.05, *q* < 0.2). **e**, Considering only the top 50 positively regulated and the top 50 negatively regulated DE genes from causarray and RUV, we map them to the top 5 biological processes (the green nodes).

nal level of 0.1 across all sample sizes and confounding lev els, while RUV-III-NB, CINEMA-OT-W, CINEMA-OT, and

els, while RUV-III-NB, CINEMA-OI-W, CINEMA-OI, and
CoCoA-diff exhibit inflated FPRs exceeding 0.5 in most cases.
Notably, causarray achieves the highest TPRs across all scenarios, with values ranging from approximately 0.8 to 0.9 depending on sample sizes and confounding levels (Fig. 2b and
Fig. S1ab). This is significantly higher than RUV-III-NB and
CoCoA-diff, which achieve TPRs below 0.5 in most settings,
particularly for smaller sample sizes or higher confounding

²⁵⁵ particularly for sinarce sample sizes of inglief conformation
 ²⁵⁶ levels. These results highlight causarray's ability to balance

sensitivity and specificity effectively.

In terms of unmeasured confounder adjustment, causarray, 258 RUV-III-NB, and CoCoA-diff achieve both ARI and ASW 259 scores consistently above 0.7 across all sample sizes in both 260 bulk and single-cell data (Fig. 2b, Fig. S1ab), outperform-261 ing RUV, CINEMA-OT-W, CINEMA-OT, which show ARI 262 scores below 0.5 in most cases. Furthermore, causarray effec-263 tively disentangles treatment effects from unmeasured con-264 founding effects. In the response space (Fig. 2d), treatment 265 groups are distinctly separated with minimal overlap, while 266

Fig. 5. Results of DE analysis of 10 selected genes by causarray. The top 5 up-regulated and top 5 down-regulated genes in estimated LFCs (adjusted P value < 0.05) are visualized. **a**, Estimated counterfactual distributions. The values are shown in the log scale after adding one pseudo-count. **b**, Estimated log-fold change of treatment effects, conditional on age for selected genes. The center lines represent the mean of the locally estimated scatter plot smoothing (LOESS) regression, and the shaded area represents a 95% confidence interval at each value of age.

variations within groups reflect unmeasured confounders. In
the confounder space (Fig. 2e), causarray produces a uniform
mixing of treatment groups while accurately reconstructing
continuous confounder values.

Finally, we assess the robustness of causarray, RUV-III-271 NB, and RUV under varying numbers of latent factors (Fig. 2c 272 and Fig. S1c). Among these methods, only causarray consis-273 tently controls FPR at nominal levels of 0.1 regardless of the 274 number of factors or sample size. In contrast, RUV-III-NB 275 exhibits inflated median FPRs exceeding 0.2 when more fac-276 tors are included (e.g., r = 6). While RUV-III-NB performs 277 well in terms of ARI (above 0.8) and ASW (above 0.7), its 278 DE testing performance is inferior to RUV due to poor FPR 279 control under certain conditions. Based on these findings, we 280 proceed with causarray and RUV for real data analysis. 281

causarray applied to an in vivo Perturb-seq study reveals causal effects of ASD/ND genes

An integrative analysis of multiple single perturbations. Autism
 spectrum disorders and neurodevelopmental delay (ASD/ND)

represent a complex group of conditions that have been ex-286 tensively studied using genetic approaches. To investigate the 287 underlying mechanisms of these disorders, researchers have 288 employed scalable genetic screening with CRISPR-Cas9 tech-289 nology (17). Frameshift mutations were introduced in the 290 developing mouse neocortex in utero, followed by single-291 cell transcriptomic analysis of perturbed cells from the early 292 postnatal brain (17). These in vivo single-cell Perturb-seq 293 data allow for the investigation of causal effects of a panel of 294 ASD/ND risk genes. We analyze the transcriptome of cortical 295 projection neurons (excitatory neurons) perturbed by one risk 296 gene or a non-targeting control perturbation, which serves as 297 a negative control. 298

Unmeasured confounders, such as batch effects and unwanted variation, are likely present in this dataset due to the batch design being highly correlated with perturbation conditions (Fig. S2ab). Additionally, the heterogeneity of single cells assessed in vivo introduces further complexity. These confounding factors may reduce statistical power for gene-

level differential expression (DE) tests, as noted in the orig-305 inal study (17), which instead focused on gene module-level 306 effects. To address this limitation, we apply causarray to in-307 corporate unmeasured confounder adjustment and conduct 308 a more granular analysis at the single-gene level. This ap-309 proach enables us to uncover nuanced genetic interactions 310 and causal effects that may provide deeper insights into the 311 etiology of ASD/ND. 312

Functional analysis. Gene module-level analyses have been 313 shown to provide greater statistical power for detecting bi-314 ologically meaningful perturbation effects when fewer cells 315 are available (17). The original study adopted this approach 316 but relied on a linear model rather than a negative binomial 317 model, potentially limiting its ability to detect broader sig-318 nals at the individual gene level. Here, we compare causarray 319 with RUV and DESeq2 (without confounder adjustment) to 320 identify significant genes and enriched gene ontology (GO) 321 terms associated with various perturbations. 322

In terms of significant gene detection, causarray identi-323 fies a comparable number of significant genes to RUV across 324 most perturbations, while DESeq2 consistently detects fewer 325 significant genes (Fig. 3a). The variation in significant de-326 tections across different perturbed genes suggests distinct bi-327 ological impacts of each knockout. Functional analysis fo-328 cuses on enriched GO terms on the DE genes under each per-329 turbation condition where discrepancies arise between causar-330 ray and other methods. Genes identified by causarray are 331 enriched for biologically relevant GO terms with clear clus-332 tering patterns (Fig. 3b-c, Fig. S2c). In contrast, RUV shows 333 less distinct clustering and enrichment patterns. 334

Notably, while RUV identifies GO terms related to ribo-335 some processes previously implicated in ASD studies (27), 336 these findings remain controversial. Some argue that dysreg-337 ulation in translation processes and ribosomal proteins may 338 reflect secondary changes triggered by expression alterations 339 in synaptic genes rather than direct causal effects (28). In 340 contrast, GO terms identified by causarray align more closely 341 with the expected causal effects of ASD/ND gene perturba-342 tions (29, 30). 343

To further validate these findings, we examine the pertur-344 bation condition for Satb2, which yields the largest num-345 ber of significant genes identified by both methods (adjusted 346 P value < 0.1). Satb2 is known to play critical roles in 347 neuronal development, synaptic function, and cognitive pro-348 cesses (31, 32). Using causarray, we detect enrichment for 349 GO terms directly related to neuronal function and develop-350 ment, such as "regulation of neuron projection development," 351 "regulation of synapse structure or activity," and "synapse 352 organization" (Fig. 3d). These findings are consistent with 353 Satb2's established roles in neuronal development and synap-354 tic plasticity (33, 34). On the other hand, RUV identifies en-355 richment for terms related to mitochondrial function and en-356 ergy metabolism, such as "mitochondrial electron transport," 357 "cellular respiration," and "ATP synthesis" (Fig. 3e). While 358 these processes are important for general cellular function, 350 they are less directly relevant to Satb2's primary biological 360 roles. 361

Overall, this analysis demonstrates that causarray provides greater specificity in detecting biologically meaningful causal effects of gene perturbations. Its ability to disentangle confounding influences while preserving relevant biological signals highlights its effectiveness in analyzing complex genomic datasets.

causarray reveals causally affected genes of Alzheimer's disease in a case-control study 369

An integrative analysis of excitatory neurons. We analyze 370 three Alzheimer's disease (AD) single-nucleus RNA sequenc-371 ing (snRNA-seq) datasets: a transcriptomic atlas from the 372 Religious Orders Study and Memory and Aging Project (ROSMAP (35) and two datasets from the Seattle Alzheimer's Disease 374 Brain Cell Atlas (SEA-AD) consortium (36), which include 375 samples from the middle temporal gyrus (MTG) and pre-376 frontal cortex (PFC). Our objective is to compare the perfor-377 mance of causarray and RUV in pseudo-bulk DE tests of AD 378 in excitatory neurons. 379

To evaluate the validity, we perform a permutation experi-380 ment on the ROSMAP-AD dataset by permuting phenotypic 381 labels. Ideally, no significant discoveries should be made un-382 der this null scenario. However, RUV produces a large num-383 ber of false discoveries, with its performance deteriorating as 384 the number of latent factors increases. In contrast, causarray 385 effectively controls the false discovery rate (FDR), producing 386 minimal false positives (Fig. 4a). Additionally, we assess co-387 herence across datasets by examining effect sizes in SEA-AD 388 (MTG) and SEA-AD (PFC). Effect sizes estimated by causar-389 ray exhibit higher consistency across varying q-value cutoffs 390 compared to RUV (Fig. 4b, Fig. S3b). When inspecting DE 391 genes across all three AD datasets, causarray identifies more 392 consistent discoveries than RUV (Fig. 4c), highlighting its 393 robustness in detecting causally affected genes. 394

Functional analysis. We further compare functional enrich-395 ment results between causarray and RUV using gene ontol-396 ogy (GO) terms associated with DE genes. Across the three 397 datasets, causarray identifies 165 common GO terms, signif-398 icantly more than the 60 identified by RUV (Fig. 4d). Both 399 methods detect GO terms relevant to neuronal development 400 and synaptic functions, which are critical for understanding 401 AD pathology. However, causarray shows distinct enrich-402 ment in categories such as "positive regulation of cell devel-403 opment" and "negative regulation of cell cycle', reflecting 404 its increased sensitivity to synaptic and neurotransmission-405 related processes. In contrast, RUV's results exhibit more 406 dataset-specific enrichments, such as biosynthetic processes 407 in SEA-AD (PFC), apoptotic processes in SEA-AD (MTG), 408 and catabolic processes in ROSMAP-AD (Fig. S3c). These 409 findings suggest that causarray captures more generalizable 410 biological signals across datasets. 411

Both methods identify overlapping top functional categories 412 related to key biological processes associated with AD pathology (Fig. S3e). However, causarray associates a larger number of genes with these categories, identifying 3393 DE genes 415 compared to 3187 for RUV (Fig. 4c). Additionally, causarray 416 reveals 165 common GO terms across the three datasets, sig-

nificantly more than the 60 identified by RUV (Fig. 4d). The 418 visualization of the discovered networks, as defined as the top 419 5 GO terms and associated genes included in the top 100 DE 420 gene discoveries, further highlights the enhanced sensitivity 421 and comprehensiveness of causarray. Specifically, the causar-422 ray network contains 17 gene nodes and 81 edges, compared 423 to 14 gene nodes and 57 edges in the RUV network (Fig. 4e). 424 This greater interconnectedness in the larger causarray net-425 work suggests a more intricate and informative representa-426 tion of underlying biological relationships, emphasizing its 427 ability to capture broader and more relevant genetic factors 428 associated with AD pathology. 429

Counterfactual analysis. The counterfactual framework em-430 ployed by causarray enables downstream analyses that di-431 rectly utilize estimated potential outcomes. By examining 432 counterfactual distributions for significant genes (Fig. 5a), we 433 observe distinct shifts in expression levels between treatment 434 (Y(1)) and control (Y(0)) groups. Downregulated genes show 435 a shift toward lower expression levels under disease condi-436 tions, while upregulated genes exhibit increased expression. 437 Conditional average treatment effects (CATEs) reveal age-438 dependent trends for these genes (Fig. 5b). For example, up-439 regulated genes such as SLC16A6 and RFLNA show stronger 440 effects at extreme ends of the age distribution, while others 441 like SLC38A2 and BAG6 display nuanced changes across the 442 aging spectrum. 443

These findings align with prior studies highlighting the 444 roles of specific genes in aging-related processes. For in-445 stance, ZFR2, RFLNA, BAG6, and RAD21 have been impli-446 cated in chromatin remodeling, synaptic plasticity, and cellu-447 lar stress responses critical for aging and neurodegeneration 448 (37–40). While nonparametric fitted curves exhibit wider un-449 certainty bands, particularly at the boundaries, which can be 450 observed here, the significant trends observed for key genes 451 highlight their potential relevance in AD pathology. Overall, 452 these results demonstrate that causarray provides nuanced in-453 sights into age-dependent gene regulation mechanisms while 454 maintaining robust control over confounding influences. 455

456 Discussion

The rapid growth of high-throughput single-cell technologies 457 has created an urgent need for robust causal inference frame-458 works capable of disentangling treatment effects from con-459 founding influences. Existing methods, such as CINEMA-460 OT (11), have advanced the field by separating confounder 461 and treatment signals and providing per-cell treatment-effect 462 estimates. However, these methods rely on the assumption 463 of no unmeasured confounders, which is often violated in 464 observational studies and in vivo experiments. Additionally, 465 many confounder adjustment methods, such as RUV (12), de-466 pend on linear model assumptions that do not directly model 467 count data or provide robust differential expression testing at 468 the gene level. Addressing these limitations, causarray intro-469 duces a doubly robust framework that integrates generalized 470 confounder adjustment with semiparametric inference to en-471 able reliable and interpretable causal analysis. 472

causarray directly models count data using generalized lin-473 ear models for unmeasured confounder estimation, overcom-474 ing a key limitation of RUV in DE analysis. Unlike CINEMA-475 OT (11) and CoCoA-diff (6), which rely on optimal transport 476 or matching techniques, causarray employs a doubly robust 477 framework that combines flexible machine learning models 478 with semiparametric inference. This approach enhances sta-479 bility and interpretability while enabling valid statistical in-480 ference of treatment effects. Benchmarking results demon-481 strate that causarray outperforms existing methods in disen-482 tangling treatment effects from confounding influences across 483 diverse experimental settings, maintaining superior control 484 over false positive rates while achieving higher true positive 485 rates. 486

In an in vivo Perturb-seq study of ASD/ND genes, causar-487 ray uncovered gene-level perturbation effects that were missed 488 by prior module-based analyses. It identified biologically rel-489 evant pathways linked to neuronal development and synaptic 490 functions for multiple autism risk genes. Similarly, in a case-491 control study of Alzheimer's disease using three human brain 492 transcriptomic datasets, causarray revealed consistent causal 493 gene expression changes across datasets and highlighted key 494 biological processes such as synaptic signaling and cell de-495 velopment. These findings underscore the ability of causar-496 ray to provide biologically meaningful insights across diverse 497 contexts. 498

Despite its strengths, causarray has certain limitations. Its 499 performance depends on the accurate estimation of unmea-500 sured confounders, which may vary with dataset complexity 501 and experimental design. Furthermore, while causarray pro-502 vides robust DE testing, its integration with advanced spatial 503 or trajectory analysis frameworks remains unexplored (41, 504 42). Future research could focus on extending causarray to 505 incorporate prior biological knowledge or extrapolate to un-506 seen perturbation-cell pairs, similar to emerging methods like 507 CPA (43). Such advancements would further enhance its ap-508 plicability in single-cell causal inference. 509

510 Methods

511 Counterfactual

Potential outcomes framework. Let $O = (A, W, Y) \in \{0, 1\} \times$ 512 $\mathbb{R}^{d_W} \times \mathbb{R}^p$ be a tuple of random vectors, where A is the bi-513 nary treatment variable (e.g., presence or absence of a dis-514 ease or perturbation), W is the vector of covariates (e.g., bi-515 ological or technical factors influencing both treatment and 516 outcome), and Y is the observed outcomes, defined as Y =517 AY(1) + (1 - A)Y(0), where Y(1) and Y(0) are the poten-518 tial outcomes under treatment and control, respectively. 519

The potential outcomes framework assumes that for each 520 individual or observation, there exist two potential outcomes: 521 one if the individual receives the treatment (Y(1)) and one if 522 they do not (Y(0)). However, only one of these outcomes can 523 be observed for each individual, depending on whether they 524 were treated (A = 1) or not (A = 0). This framework allows 525 us to define causal effects in terms of these unobservable po-526 tential outcomes. 527

To estimate causal effects, we rely on the following key assumptions:

Assumption 1 (Consistency) The observed response is consistent such that Y(a) = Y | A = a.

Assumption 2 (Positivity) The propensity score $\pi_a(W) := \mathbb{P}(A = a \mid W) \in (\epsilon, 1 - \epsilon)$ for some $\epsilon \in (0, 1/2)$.

Assumption 3 (No unmeasured confounders) $A \perp Y(a) \mid W$, for all $a \in \{0, 1\}$.

Under these assumptions (Assumptions 1–3), the observed outcome Y is conditionally independent of the treatment A, given the covariates W. This allows us to estimate the expected potential outcome for gene j under treatment (a = 1)or control (a = 0) as:

$$\mathbb{E}[Y_j(a)] = \psi_j(W, a) := \mathbb{E}[\mu_j(W, a)],$$

5

54

where $\mu_j(W, a) = \mathbb{E}[Y_j | W, A = a]$ is a regression function that models the relationship between covariates, treatment, and outcomes.

Suppose we have a dataset $\mathcal{D} = \{O_1, \dots, O_n\}$ consisting of i.i.d. samples from the same distribution as O. Let \mathbb{P}_n denote the empirical measure over \mathcal{D} , defined as:

$$\mathbb{P}_n f(O) = n^{-1} \sum_{i=1}^n f(O_i)$$

for any measurable function f. This represents the sample average of a function evaluated on all observations in the dataset.

⁵⁵² A naive plug-in estimator for ψ_j can then be constructed ⁵⁵³ by replacing the true regression function $\mu_j(W, a)$ with its ⁵⁵⁴ estimated counterpart $\hat{\mu}_j(W, a)$ and using sample averages to ⁵⁵⁵ approximate expectations. The resulting estimator is:

$$\widehat{\psi}_j^{\mathrm{PI}} = \mathbb{P}_n[\widehat{\mu}_j(W, a)] = n^{-1} \sum_{i=1}^n \widehat{\mu}_j(W_i, a).$$

This plug-in estimator provides an estimate of the expected
 potential outcome by averaging predictions from the estimated
 regression model over all observations in the dataset.

While Assumptions 1–3 are foundational for causal infer-560 ence, violations of the no unmeasured confounders assump-561 tion (Assumption 3) are common in real-world applications 562 (18, 19). For instance, in single-cell transcriptomic studies, 563 technical factors such as batch effects or biological hetero-564 geneity (e.g., cell size or cell cycle stage) may act as unmea-565 sured confounders. These unmeasured variables can bias es-566 timates of causal effects by introducing spurious associations 567 between treatment and outcome. Addressing this limitation 568 motivates the need for methods that explicitly model and ad-569 just for unmeasured confounders. 570

The probabilistic modeling of confounders. To account for 571 unmeasured confounders, we propose an improved version of 572 the GCATE method (18), which identifies potential unmea-573 sured confounders under generalized linear models (GLMs). 574 This approach extends traditional confounder adjustment meth- 575 ods by incorporating more flexible nonlinear models that bet-576 ter capture the unique characteristics of genomic count data, 577 such as zero-inflation (an excess of zero counts) and over-578 dispersion (greater variability than expected under standard 579 Poisson assumptions). These enhancements allow for more 580 accurate modeling of gene expression data, addressing limi-581 tations of simpler linear models in high-dimensional genomic 582 analyses. 583

For the *i*th observation (e.g., a single cell or sample) and 584 the *j*th gene, we model the adjusted expression $\mu_{ij} = Y_{ij}/s_j$, 585 where Y_{ij} is the observed expression level, and s_j is the size 586 factor for the *j*th gene. The size factor accounts for differ-587 ences in sequencing depth or library size across samples, en-588 suring that comparisons are not biased by technical variabil-589 ity. We assume that μ_{ij} follows an exponential family dis-590 tribution, which is a flexible class of probability distributions 591 commonly used in GLMs. The density of μ_{ij} is given by: 592

$$p(\mu_{ij} \mid \theta_{ij}) = h(\mu_{ij}) \exp\left(\mu_{ij}\theta_{ij} - A(\theta_{ij})\right),$$
593

where θ_{ij} is the natural parameter that determines the mean and variance of μ_{ij} , $h(\mu_{ij})$ is a known base measure, and $A(\theta_{ij})$ is the log-partition function, which ensures that the density integrates to 1.

In matrix form, we model the natural parameters

$$\boldsymbol{\Theta} = (\theta_{ij})_{1 \le i \le n, 1 \le j \le p},$$

598

600

as a decomposition into two components:

$$\Theta = \widetilde{X}B^{ op} + U\Gamma^{ op}.$$
 60

Here, $\widetilde{X} = [X, A] \in \mathbb{R}^{n \times (d+1)}$ combines observed covari-602 ates X (e.g., biological or technical factors) with treatment 603 indicators A, where n is the number of observations, and d604 is the dimension of X; $B \in \mathbb{R}^{p \times (d+1)}$ represents unknown 605 regression coefficients for the effects of covariates and treat-606 ments on gene expression; $U \in \mathbb{R}^{n \times r}$ represents latent vari-607 ables capturing unmeasured confounders, where r is the num-608 ber of latent factors; and $\mathbf{\Gamma} \in \mathbb{R}^{p \times r}$ represents unknown coef-609 ficients linking unmeasured confounders to gene expression. 610

672

673

697

698

699

This decomposition assumes that gene expression levels are influenced by both observed covariates (\widetilde{X}) and unmeasured confounders (U). The term $\widetilde{X}B^{\top}$ captures the effects of observed covariates and treatments, while $U\Gamma^{\top}$ captures the effects of unmeasured confounders.

To estimate these unknown quantities (B, U, Γ) , we em-616 ploy methods detailed in Appendix S1. This includes tech-617 niques for estimating latent factors (U) and extending the 618 framework to handle multiple treatments. Once these quan-619 tities are estimated, we treat $W = [X, \widehat{U}] \in \mathbb{R}^{d+r}$ as the 620 complete set of confounding covariates-combining both ob-621 served covariates (X) and estimated unmeasured confounders 622 (U).623

With this expanded set of covariates, we perform doubly robust estimation and inference as described in subsequent sections. This approach ensures that treatment effects are estimated while accounting for both observed and unmeasured confounding influences, improving robustness and reliability in causal inference.

Doubly robust estimation. Throughout the paper, we consider
 the log fold change (LFC) as the target estimand:

$$\tau_j := \log(\mathbb{E}[Y_j(1)]/\mathbb{E}[Y_j(0)])$$

6

which quantifies the relative change in expected gene expression levels between treatment (A = 1) and control (A = 0)conditions for gene *j*. Extensions to other estimands are provided in Appendix S2.

⁶³⁷ The doubly robust estimation framework is a widely used ⁶³⁸ approach that is agnostic to the underlying data-generating ⁶³⁹ process. It provides valid estimation and inference results as ⁶⁴⁰ long as either the conditional mean model (μ_j) or the propen-⁶⁴¹ sity score model (π) is correctly specified. This robustness ⁶⁴² property ensures reliable causal effect estimation even in the ⁶⁴³ presence of potential misspecification of one of the models.

More specifically, a one-step estimator $\hat{\tau}_j$ of the estimand 45 τ_j admits a linear expansion:

646
$$\widehat{\tau}_j - \tau_j = \frac{1}{n} \sum_{i=1}^n \eta_j(O_i; \pi, \mu_j) + o_{\mathbb{P}}(n^{-1/2}),$$

where $\eta_j(O_i; \pi, \mu_j)$ is the influence function of τ_j , which quantifies how individual observations contribute to the overall estimate. Here, $\pi(\mathbf{W}) = \mathbb{P}(A = a \mid \mathbf{W})$ is the propensity score model, and $\mu_j(\mathbf{W}, a) = \mathbb{E}[Y_j \mid W, A = a]$ is the outcome model for gene j. See Appendix S2 for detailed derivations of these functions.

To estimate the nuisance functions μ_i 's (outcome models) 653 and π (propensity score model), we use flexible statistical 654 machine learning methods. Specifically, for outcome mod-655 els μ_j , we employ generalized linear models (GLMs) with 656 a negative binomial likelihood and log link function. This 657 choice accounts for over-dispersion in count data while en-658 suring computational efficiency given the high dimensional-659 ity of genomic data. For the propensity score model π , we 660 provide two built-in options: (i) logistic regression and (ii) 661

random forests. In our experiments, random forests are configured with 1,000 trees, a minimum leaf size of 3, and a maximum tree depth of 11. Extrapolated cross-validation (ECV) (44) is used to select hyperparameters by minimizing the estimated mean squared error. Users can also supply alternative estimates for these nuisance functions if desired.

To perform inference, we first compute the estimated influence function values $\hat{\eta}_j(O_i; \hat{\pi}, \hat{\mu}_j)$ and use them to estimate the variance for gene j:

$$\widehat{\sigma}_j^2 = \frac{\sqrt{n}}{n-1} \sum_{i=1}^n \widehat{\eta}_j (O_i; \widehat{\pi}, \widehat{\mu}_j)^2.$$

Using these quantities, a t-statistic for gene j can be computed as:

$$T_j = \frac{\widehat{\tau}_j - \tau_j}{\widehat{\sigma}_j}.$$

This statistic enables hypothesis testing and confidence interval construction for causal effects on gene expression.

False discovery rate control. Genomic studies often involve 677 testing thousands of hypotheses simultaneously, making it 678 crucial to control statistical Type-I errors. Two widely rec-679 ognized error rate metrics are the Family-Wise Error Rate 680 (FWER) and the False Discovery Rate (FDR), each suited 681 to different contexts. Consider p hypothesis tests, let $S \subset$ 682 $\{1,\ldots,p\}$ denote the set of discoveries, and $\mathcal{H}_0 \subset \{1,\ldots,p\}$ 683 denote the set of true null hypotheses. The false discovery 684 proportion (FDP) is defined as the ratio of false positives to 685 total discoveries: 686

$$FDP = \frac{|\mathcal{S} \cap \mathcal{H}_0|}{|\mathcal{S}| \vee 1}.$$
687

The FWER controls the probability of making at least one false discovery: 688

where $\alpha \in (0, 1)$ is a predefined significance level. This stringent control is particularly useful in scenarios where even a single false positive is unacceptable. However, FWER control often leads to reduced statistical power, especially in highdimensional settings with many hypotheses, potentially overlooking true effects.

In contrast, FDR control provides a more balanced approach by controlling the expected proportion of false discoveries among all discoveries:

$$FDR := \mathbb{E}[FDP] \le \alpha.$$
 700

This approach enhances power in multiple testing scenarios 701 and has become the standard for differential expression anal-702 ysis in genomics due to its ability to identify more significant 703 features while maintaining a low proportion of false positives 704 (45). Importantly, FDR controls the expected proportion of 705 false discoveries across repeated experiments but does not 706 guarantee bounds on FDP in any single experiment. This dis-707 tinction becomes critical in genomic studies where test statis-708 tics are often highly dependent, leading to variability in FDP 709 across experiments. 710 To address limitations of standard FDR procedures, such

⁷¹² as their inability to capture FDP variability in a single exper-

713 iment, alternative error control metrics like False Discovery

⁷¹⁴ Exceedance (FDX) have been proposed:

715

$$FDX := \mathbb{P}(FDP \ge c) \le \alpha,$$

⁷¹⁶ for a threshold $c \in (0, 1)$. FDX provides stricter control by ⁷¹⁷ limiting the probability that FDP exceeds a predefined thresh-⁷¹⁸ old c. This makes it particularly useful in applications where ⁷¹⁹ minimizing false positives is critical or when restricting anal-⁷²⁰ ysis to a small subset of discoveries is desired.

To ensure robust error rate control tailored to genomic ap-721 plications, causarray implements two complementary strate-722 gies for FDR control: (i) Benjamini-Hochberg (BH) Proce-723 dure: The BH procedure (45) is applied directly to P-values 724 obtained from the doubly robust estimation framework. BH 725 controls the FDR under independence or specific positive de-726 pendence structures among test statistics. (ii) Gaussian Mul-727 tiplier Bootstrap: For tighter control of FDP variability, par-728 ticularly when test statistics are highly dependent, causarray 729 incorporates a Gaussian multiplier bootstrap approach (Al-730 gorithm S2). This method simulates null distributions to esti-731 mate FDP more accurately and provides robust FDR control 732 even under complex dependence structures (7). 733

The choice between BH and Gaussian multiplier bootstrap 734 depends on the dependency structure among test statistics. 735 While BH is computationally efficient and widely used, it 736 may not adequately control FDR under strong dependencies. 737 The Gaussian multiplier bootstrap, on the other hand, ac-738 counts for complex dependency structures and provides more 739 accurate bounds on FDP variability. Additionally, incorpo-740 rating FDX offers an extra layer of conservatism for applica-741 tions where minimizing false positives is critical. By offering 742 these complementary strategies, causarray ensures robust er-743 ror rate control tailored to diverse genomic applications while 744 balancing power and error control. 745

746 Data simulation and analysis

We consider two simulation settings. In the first simulation,
we generate cells from zero-inflated Poisson distributions. In
the second simulation, we use a specialized single-cell simulator Splatter (25) to generate cells with batch effects. Both
simulations include 1 observed covariate and 4 unmeasured
confounders. The details of the simulation are provided in
Appendix S3.

Benchmarking methods. To evaluate the performance of dif ferential expression (DE) testing, we compare causarray with
 several established methods, both with and without confounder
 adjustment. These methods are grouped into two categories
 based on whether they account for unmeasured confounders.

760 Methods without confounder adjustment include:

Wilcoxon rank-sum test: This nonparametric test is applied to deviance residuals obtained by regressing gene expression counts on measured covariates using a negative binomial generalized linear model (GLM). The

deviance residuals serve as input for the test, which 765 does not explicitly account for unmeasured confounders. 766

DESeq2 (26): This widely used method fits a negative binomial GLM to gene expression counts and adjusts for measured covariates. However, it does not account for unmeasured confounders, which may bias results in the presence of hidden variation.

772

Methods with confounder adjustment include:

- CoCoA-diff (R package mmutilR 1.0.5) (6): Designed for individual-level case-control studies, CoCoAdiff prioritizes disease genes by adjusting for confounders 775 estimated from parametric models. After adjusting for these confounders, the Wilcoxon rank-sum test is applied to the adjusted residuals, as recommended in the original paper. 779
- CINEMA-OT (Python package cinemaot 0.0.3) 780 (11): CINEMA-OT separates confounding sources of 781 variation from perturbation effects using optimal transport matching to estimate counterfactual cell pairs. Similar to CoCoA-diff, the Wilcoxon rank-sum test is applied to the adjusted residuals of CINEMA-OT. 785
- RUV-III-NB (R package ruvIIInb 0.8.2.0) (13): 786 This method normalizes gene expression data using pseudo replicates and a negative binomial model to remove un-788 wanted variation induced by library size differences. 789 The Kruskal-Wallis test (equivalent to the Wilcoxon 790 test for two-group comparisons) is then applied to log-791 percentile adjusted counts, as suggested by the authors. 792 However, RUV-III-NB does not directly adjust for li-793 brary size and its ability to control FDR remains un-794 clear, as it was not demonstrated in their experiments. 795
- RUV (R package ruv 0.9.7.1) (12): RUVr is used 796 to estimate unmeasured confounders, which are then 797 incorporated into DESeq2 for statistical inference based 798 on both observed and estimated covariates. Before run-799 ning RUV, we successively use the functions 800 calcNormFactors, estimateGLMCommonDisp, 801 estimateGLMTagwiseDisp, and glmFit of edgeR $_{\rm 802}$ package (4.0.16) (46) to extract residuals not explained 803 by observed covariates and treatments. 804

This comprehensive benchmarking enables a thorough eval-
uation of each method's ability to address unmeasured con-
founder estimation and perform robust statistical inference in
simulated data settings.805
806807808

Evaluation metrics.To compare the performance of different809methods, we use four evaluation metrics, focusing on two aspects: confounder estimation and biological signal preservation.810tion.DESeq2 and Wilcoxon are excluded from confounder812estimation evaluation as they do not estimate unmeasured813confounders or counterfactuals.814

The performance of confounder estimation is assessed using two clustering-based metrics: Adjusted Rand Index (ARI) and Average Silhouette Width (ASW) (47). These metrics evaluate the quality of mixing in response and confounder spaces, respectively. Formally, measures the similarity between the clustering results based on the estimated control responses Y(0) and the true cell-type labels of the same samples. It adjusts for similarities that occur by chance:

$$ARI = \frac{\sum_{ij} \binom{n_{ij}}{2} - [\sum_{i} \binom{a_{i}}{2} \sum_{j} \binom{b_{j}}{2}]/\binom{n_{j}}{2}}{\frac{1}{2} [\sum_{i} \binom{a_{i}}{2} + \sum_{j} \binom{b_{j}}{2}] - [\sum_{i} \binom{a_{i}}{2} \sum_{j} \binom{b_{j}}{2}]/\binom{n_{j}}{2}}$$

where n is the total number of samples, n_{ij} is the number 824 of samples in both cluster i and partition j, a_i is the sum 825 over rows in the contingency table, and b_i is the sum over 826 columns. Higher ARI values indicate better conservation of 827 cell identity based on estimated counterfactuals compared to 828 true labels. ARI ranges from -1 (complete disagreement) to 820 1 (perfect agreement), with 0 indicating random clustering. 830 On the other hand, ASW quantifies how well each sample 831 fits within its assigned cluster compared to other clusters. It 832 is defined as: 833

ASW =
$$\frac{1}{n} \sum_{i=1}^{n} \frac{b(i) - a(i)}{\max\{a(i), b(i)\}}$$

where a(i) is the average dissimilarity of sample *i* to all other samples within its cluster, and b(i) is the average dissimilarity to samples in the nearest neighboring cluster. ASW values range from -1 to 1, with higher values indicating betterdefined clusters (47). For both metrics, median scores are scaled between 0 and 1 across methods within each simulation setup. For these two metrics, we use the implementations from the scib (1.1.5) package (47).

To evaluate biological signal preservation, we use False
Positive Rate (FPR) and True Positive Rate (TPR), which are
standard metrics derived from confusion matrices: PR quantifies the proportion of false positives among all true negatives:

$$FPR = \frac{FP}{FP + TN},$$

where FP and TN are false positives and true negatives, respectively. A lower FPR indicates fewer false discoveries relative to true negatives. Also known as sensitivity or recall,
TPR measures the proportion of true positives among all actual positives:

$$TPR = \frac{11}{TP + FN},$$

848

where TP and FN are true positives and false negatives, respectively. A higher TPR indicates better detection of true
signals. These metrics provide complementary insights: FPR
evaluates specificity by penalizing false discoveries, while
TPR assesses sensitivity by rewarding correct detections. Together, they measure how well a method balances identifying
true signals while avoiding false discoveries.

862 Single-cell Perturb-Seq dataset

We utilize the Perturb-Seq dataset from (17), which enables
 high-resolution transcriptomic profiling of genetic perturba tions in excitatory neurons. This scalable platform system atically investigates gene functions across diverse cell types

and perturbation conditions, providing critical insights into neurodevelopmental processes (17). We focus on excitatory neurons of the dataset, a key population implicated in neurodevelopmental disorders such as autism spectrum disorders and neurodevelopmental delay, with perturbations targeting genes involved in neuronal development and synaptic function (17).

For preprocessing, we filter out cells with perturbations 874 measured in fewer than 50 cells and genes expressed in fewer 875 than 50 cells, resulting in a dataset containing 2926 cells un-876 der 30 perturbation conditions. The GFP (Green Fluorescent 877 Protein) condition is used as a negative control to benchmark 878 the effects of other perturbations by providing a baseline for 879 comparison in downstream analyses. After filtering lowly ex-880 pressed genes with a maximum count of fewer than 10, we 881 retain 3221 genes. 882

The batch design is highly correlated with perturbation conditions; therefore, it is not included as a covariate in the model for testing. Instead, only the intercept is included as a covariate. For propensity score estimation, we incorporate the logarithm of library sizes as an additional covariate to account for technical variability and use GLM as the propensity score model.

Single-nucleus Alzheimer's disease dataset

This study integrates data from three single-nucleus RNA 891 sequencing (snRNA-seq) datasets to investigate Alzheimer's 892 disease (AD): the ROSMAP-AD dataset (35) and two datasets 893 from the Seattle Alzheimer's Disease Brain Cell Atlas (SEA-894 AD) consortium (36), covering the middle temporal gyrus 895 (MTG) and prefrontal cortex (PFC). These datasets provide 896 complementary insights into AD pathology across different 897 brain regions and donor cohorts. 898

The ROSMAP-AD dataset is derived from a single-nucleus 899 transcriptomic atlas of the aged human prefrontal cortex, in-900 cluding 2.3 million cells from postmortem brain samples of 901 427 individuals with varying degrees of AD pathology and 902 cognitive impairment (35). To ensure a balanced representa-903 tion across subjects, we perform stratified down-sampling of 904 300 cells per subject, focusing on excitatory neurons while 905 excluding two rare subtypes ('Exc RELN CHD7' and 'Exc 906 NRGN'). This preprocessing results in a dataset with 124997 907 cells and 33538 genes. 908

Next, we create pseudo-bulk gene expression profiles by 909 aggregating gene expression counts across cells for each subject. Genes expressed in fewer than 10 subjects are filtered 911 out, resulting in a final dataset of 427 samples and 26,106 912 genes. Binary treatment is defined based on the variable 'age_first_iad_dx',

which approximates the "age at the time of onset of Alzheimer's ⁹¹⁴ dementia." Covariates included in the analysis are 'msex' (biological sex), 'pmi' (postmortem interval), and 'age_death' ⁹¹⁶ (age at death). Missing values for 'pmi' are imputed using ⁹¹⁷ the median of observed values. ⁹¹⁸

The SEA-AD data are obtained from a multimodal cell atlas of AD developed by the Seattle Alzheimer's Disease Brain Cell Atlas (SEA-AD) consortium (36). This resource includes snRNA-seq datasets from two brain regions: the

middle temporal gyrus (MTG) and prefrontal cortex (PFC), 923

covering 84 donors with varying AD pathologies. 924

- For both MTG and PFC datasets, we perform stratified 925 down-sampling of 300 cells per subject, focusing on exci-926
- tatory neurons. Pseudo-bulk gene expression profiles are cre-927
- ated by aggregating counts across cells for each subject. Genes 928
- expressed in fewer than 40 subjects are filtered out, result-929
- ing in final datasets with: 80 samples and 24,621 genes for 930
- MTG and 80 samples and 25,361 genes for PFC. Covariates 931
- included in the analysis are 'sex', 'pmi', and 'Age_at_death'. 932 These variables account for biological and technical variabil-
- 933

ity across donors. 934

- To enable comparative analyses across the three datasets 935 (ROSMAP-AD, SEA-AD MTG, and SEA-AD PFC), we re-936
- strict the analysis to 15586 common genes that are expressed 937
- in all three datasets. Genes with a maximum expression count 938 below 10 among subjects are excluded to ensure robust com-939
- parisons. 940

CODE AVAILABILITY 941

The code for reproducing the results in the paper and the causarray package 942 943 can be accessed at https://github.com/jaydu1/causarray.

944 DATA AVAILABILITY

- All datasets used in this paper are previously published and freely available, ex-945 cept the metadata for donors from the ROSMAP cohort. The Perturb-seq dataset is available through the Broad single cell portal as txt files. The gene expression 947 count matrices of ROSMAP-AD datasets (35) can be obtained from supplementary 948
- website, which have been deidentified to protect confidentiality the mapping to 919
- ROSMAP IDs and complete metadata can be found on Synapse as Seurat objects
- (rds files). The SEA-AD datasets of nuclei-by-gene matrices with counts and nor-951
- malized expression values from the snRNA-seq assay (36) are available through 952
- the Open Data Registry in an AWS bucket (sea-ad-single-cell-profiling) as AnnData 953 objects (h5ad files). 954

ACKNOWLEDGEMENTS 955

This work used the Bridges-2 system at the Pittsburgh Supercomputing Center 956 (PSC) through allocation MTH230011P from the Advanced Cyberinfrastructure Co-957 ordination Ecosystem: Services & Support (ACCESS) program. Supplementary Note S1: Confounder estimation

1132 Comparison with reference-based confounder adjustment methods

Another approach to adjust for the unmeasured confounders is to utilize the information from negative control genes. This

includes scMerge (48), RUV-III-NB (13) and RUVSeq (12) etc. These methods require users to specify a set of negative

control genes, such as housekeeping genes, which are assumed to be solely due to unwanted variation between the two cells. The approach necessitates strong prior knowledge to accurately identify negative control genes, which may not always be

¹¹³⁶ The approach necessitates strong prior knowledge to accurately identify negative control genes, which may not always be ¹¹³⁷ available, especially in less well-characterized biological systems. This reliance on prior knowledge can limit the applicability

¹¹³⁸ of the method in novel or poorly understood contexts.

1139 Algorithm

To estimate the unmeasured confounders, we employ an improved version of GCATE (18). Suppose (X_i, A_i, Y_i) for i = 1, ..., nare *n* independently and identically distributed samples coming from the same distribution as $(X, A, Y) \in \mathbb{R}^d \times \mathbb{R}^a \times \mathbb{R}^p$. Here, *A* consists of *a* treatments and can be both continuous and discrete for the purpose of confounder estimation. Let $X \in \mathbb{R}^{n \times d}, A \in \mathbb{R}^{n \times a}, Y \in \mathbb{R}^{n \times p}$ denote the design matrix, treatment matrix and gene expression matrix, respectively. To account for different library sizes, we model the mean of the size-normalized counts

$$\mu_{ij} = \frac{Y_{ij}}{s_i},$$

which is assumed to follow a negative binomial distribution. Technically, μ_{ij} 's should be non-negative integers; however, the likelihood-based approaches work seamlessly even when they are non-negative real numbers. Here s_i is the size factor of cell *i*, which will be specified later. We assume the conditional mean is characterized by a generalized linear model

$$\log \mu_{ij} \sim A_i + X_i + U_i$$

and its dispersion parameter ϕ is predetermined.

The adjusted expression μ_{ij} of the *i*th observation and the *j*th gene has the density:

$$p(\mu_{ij} \mid \theta_{ij}) = h(\mu_{ij}) \exp\left(\mu_{ij}\theta_{ij} - A(\theta_{ij})\right),$$

where θ_{ij} is the natural parameter. In matrix form, the natural parameters decompose as

$$\Theta = \widetilde{X}B^{ op} + U\Gamma^{ op}$$

1152

1149

where $\widetilde{X} = [X, A] \in \mathbb{R}^{n \times (d+a)}$, $B \in \mathbb{R}^{p \times (d+a)}$, $U \in \mathbb{R}^{n \times r}$, and $\Gamma \in \mathbb{R}^{p \times r}$ are unknown. Note that μ_{ij} 's are conditionally independent given the natural parameter Θ . With this notation, the procedure of unmeasured confounder estimation is summarized in Algorithm S1, and the details of the method are described below.

Estimation of size factors. We follow the procedure in (26) to compute the size factors s_i for i = 1, ..., n. We start by calculating the geometric mean for each gene j:

1162

$$g_j = \exp\left(\frac{\sum_i \log(Y_{ij}) \mathbbm{1}\{Y_{ij} > 0\}}{\sum_i \mathbbm{1}\{Y_{ij} > 0\}}\right).$$

Next, for each sample i, compute the initial size factors:

1160
$$d_i = \exp\left(\underset{j:Y_{ij}>0}{\operatorname{median}} \{ \log(Y_{ij}) - \log(g_j) \} \right).$$

¹¹⁶¹ Finally, we normalize these size factors to have a geometric mean of 1 across all samples:

$$s_i = \frac{d_i}{(\prod_i d_i)^{1/n}}.$$
(S1)

The size factors can then be used to normalize gene expression data, adjusting for differences in sequencing depth and other sys-

tematic biases across samples. The normalization ensures that observed differences in expression levels reflect true biological variation rather than technical artifacts.

Algorithm S1 Unmeasured confounder estimation

Input: A data matrix $Y \in \mathbb{R}^{n \times p}$, a design matrix $\widetilde{X} = [X, A] \in \mathbb{R}^{n \times (d+a)}$, a natural number $r \ge 1$ (the number of latent factors), a constant $C = 2 \times 10^3$ for the norm constraint

- 1: (Estimation of size factors) Compute $s \in \mathbb{R}^n$ according to Eq. (S1).
- 2: (Estimation of dispersion parameters) Compute $\phi \in \mathbb{R}^p$ according to Eq. (S2).
- 3: (Estimation of marginal effects F and uncorrelated latent components $W\Gamma^{\top}$) Solve optimization problem Eq. (S3) to obtain $\widehat{W}_0\widehat{\Gamma}_0^{\top}$ and the initial estimate of the natural parameter matrix $\widehat{\Theta}_0 = \widetilde{X}\widehat{F}^{\top} + \widehat{W}_0\widehat{\Gamma}_0^{\top}$ by alternative maximization:

$$\widehat{F}, \widehat{W}_{0}, \widehat{\Gamma}_{0} \in \operatorname*{argmin}_{F \in \mathbb{R}^{p \times (d+a)}, W \in \mathbb{R}^{n \times r}, \Gamma \in \mathbb{R}^{p \times r}} \mathcal{L}(\widetilde{X}F^{\top} + W\Gamma^{\top})$$
subject to $\widetilde{X}F^{\top} + W\Gamma^{\top} \in \mathcal{B}^{n \times p}_{C}, \qquad \mathcal{P}_{\widetilde{X}}W = \mathbf{0}.$
(S3)

- 4: (Estimation of latent coefficients Γ) Set $\widehat{W} := \sqrt{n} Q \Sigma^{1/2}$ and $\widehat{\Gamma} := \sqrt{p} V \Sigma^{1/2}$, where $\widehat{W}_0 \widehat{\Gamma}_0^\top = \sqrt{np} Q \Sigma V^\top$ is the condensed SVD with $Q \in \mathbb{R}^{n \times r}$, $\Sigma \in \mathbb{R}^{r \times r}$, $V \in \mathbb{R}^{p \times r}$.
- 5: (Estimation of direct effects B and latent factors U) Solve optimization problem Eq. (S4) to obtain $(\widehat{B}, \widehat{U})$:

$$\widehat{B}, \widehat{U} = \operatorname*{argmin}_{B \in \mathbb{R}^{p \times (d+a)}, U \in \mathbb{R}^{p \times r}} \mathcal{L}(\widetilde{X}B^{\top} + U\widehat{\Gamma}^{\top}) + \sum_{j=1}^{p} \lambda_{j} \|B_{\cdot j}\|_{1}$$
subject to
$$\widetilde{X}B^{\top} + U\widehat{\Gamma}^{\top} \in \mathcal{B}_{C}^{n \times p}, \qquad \mathcal{P}_{\widehat{\Gamma}}B = \mathbf{0}.$$
(S4)

Output: Return the estimated confounders \widehat{U} .

Estimation of dispersion parameters. To estimate the dispersion parameter, we first fit generalized linear models (GLMs) on the data and obtain the estimated mean expression of gene j, denoted as $\hat{\nu}_j$ for j = 1, ..., p. Note that when μ_{ij} comes from a Negative Binomial distribution, its variance is given by 1168

$$\operatorname{Var}(\mu_{ij} \mid \theta_{ij}) = \nu \left(1 + \alpha_j \nu\right), \tag{1169}$$

where $\nu = \mathbb{E}[\mu_{ij} | \theta_{ij}]$ is the conditional mean while α_j is the dispersion parameter of the NB1 form. In the form of exponential family parameterized by the parameter ϕ_j , α_j is the reciprocal of ϕ_j , namely, $\alpha_j = 1/\phi_j$. By methods of moments, we can solve the following equation to obtain an estimator $\hat{\phi}_j$ for ϕ_j :

$$\frac{1}{n}\sum_{i=1}^{n}(y_{ij}-\widehat{\nu}_j)^2=\widehat{\nu}_j\left(1+\alpha\widehat{\nu}_j\right).$$

Finally, we clip $\hat{\alpha}_j$ to be in $[10^{-2}, 10^2]$ and set $\hat{\phi}_j = 1/\hat{\alpha}_j$. The estimated dispersion parameter has a close-form expression:

$$\phi_j = \min\left\{ \max\left\{ \frac{\hat{\nu}_j^2}{\frac{1}{n} \sum_{i=1}^n (y_{ij} - \hat{\nu}_j)^2 - \hat{\nu}_j}, 0.01 \right\}, 100 \right\}.$$
(S2) 1175

Estimation of marginal effects by joint likelihood estimation. The negative log-likelihood function of the data is given by

$$\mathcal{L}(\boldsymbol{\Theta}) = \mathcal{L}(\boldsymbol{B}, \boldsymbol{U}, \boldsymbol{\Gamma}) = -\frac{1}{n} \sum_{i=1}^{n} \sum_{j=1}^{p} \left(\mu_{ij} \theta_{ij} - A(\theta_{ij}) + \log \left(\frac{\mu_{ij} + \phi_j - 1}{\mu_{ij}} \right) \right).$$

Although this is a nonconvex optimization problem, an alternative descent algorithm as in (18) can be employed to solve it the efficiently. By rewriting $\Theta = \widetilde{X}B^{\top} + Z\Gamma^{\top}$ as $\Theta = \widetilde{X}F^{\top} + W\Gamma^{\top}$ with $\mathcal{P}_{\widetilde{X}}W = 0$, we can disentangle the marginal effects the uncorrelated latent components. This is correspond to step 3 of Algorithm S1. Each entry of the estimated natural parameter matrix is constrained within the Euclidean ball \mathcal{B}_C with radius C ($C = 2 \times 10^3$ by default).

Before alternative maximization, we compute deviance residuals R from the NB GLM fits with offsets $\log s$ and dispersion parameters ϕ , and initialize the uncorrelated confounders by $W = \mathcal{P}_X^{\perp} U_R$ where $U_R \in \mathbb{R}^{n \times r}$ contains the first r left singular vectors of R. Here, the projection \mathcal{P}_X^{\perp} ensures that W is uncorrelated with X. Then, we initialize the marginal effects F and latent coefficient Γ by solving GLMs with covariates $[\widetilde{X}, W]$. In particular, when the intercept is included in the covariates, the initial value of W also has zero means per column.

Estimation of latent coefficients. Because the (uncorrelated) latent factors are identifiable only up to scaling and rotations, we rescle the estimate at step 4 of Algorithm S1. This ensures the eigenvalues of \widehat{W} and $\widehat{\Gamma}$ have the same order, making the alternative optimization more stable.

Estimation of confounding effects by adaptive penalization. The last step is to jointly recover the direct effects and the unmeasured confounders. This is done by imposing orthogonality between \hat{B} and $\hat{\Gamma}$, as well as imposing sparsity on \hat{B} . The former ensures the gene-wise effects of the observed covariates and the unmeasured confounders are uncorrelated, while the latter aims to reveal signals from noisy measurements.

¹¹⁹⁴ The direct effect B is initialized as $\mathcal{P}_{\widehat{\Gamma}}^{\perp}\widehat{F}$. Then, Initialize Z and Γ using the SVD of the matrix $X\widehat{F}^{\top}\mathcal{P}_{\widehat{\Gamma}} + \widehat{W}\widehat{\Gamma}^{\top} =$ ¹¹⁹⁵ $U'\Sigma'V'^{\top}$. Let $Z = (U'\Sigma'^{1/2})_{1:r}$ and $\Gamma = (V'\Sigma'^{1/2})_{1:r}$ be the initialized values.

To account for different scales of the effects induced by different treatment conditions, we propose to use the adaptive lasso to induce sparsity of effects from multiple treatments. More specifically, the regularization parameters are set as $\lambda_j = \lambda/\|(\mathcal{P}_{\widehat{\Gamma}}^{\perp}\widehat{F})_{\cdot j}\|_1$ for j = 1, ..., p in optimization problem S4.

Because of regularization, the estimate \hat{B} is typically biased towards zero, so we don't use it for downstream analysis. It is possible to perform inference with additional debiasing procedure (18). However, we use a more flexible semiparametric inference method, as described below.

1202 Determine the number of latent factors *r*

To determine the number of unmeasured confounders r, one can use the joint-likelihood-based information criterion (JIC) (18).

¹²⁰⁴ The JIC value is the sum of deviance and a penalty on model complexity:

$$\operatorname{JIC}(\widehat{\boldsymbol{\Theta}}^{(r)}) = -2\sum_{i=1}^{n}\sum_{j=1}^{p}\log p(\mu_{ij} \mid \widehat{\theta}_{ij}^{(r)}) + c_{\operatorname{JIC}} \cdot \frac{(d+a+r)\log(n \wedge p)}{n \wedge p},$$

where $\widehat{\Theta}^{(r)}$ is the estimated natural parameter matrix with r unmeasured confounders and d + a observed covariates, and $c_{\text{IIC}} > 0$ is a universal constant set to be 1 by default.

Supplementary Note S2: Doubly robust inference

Target estimands

For semiparametric inference, a target estimand is a distributional functional of the observed random variables. For example, we can consider the average treatment effects (ATE), the standardized average treatment effect (SATE), the average treatment effect in levels or fold change (FC), and the log fold change (LFC). Below, we define these estimands:

• ATE:
$$\tau_j^{\text{ATE}} = \mathbb{E}[Y_j(1) - Y_j(0)].$$

• SATE:
$$\tau_j^{\text{SATE}} = \mathbb{E}[Y_j(1) - Y_j(0)] / \sqrt{\operatorname{Var}(Y_j(0))}.$$

• ATE in levels:
$$\tau_j^{\text{FC}} = \mathbb{E}[Y_j(1) - Y_j(0)] / \mathbb{E}[Y_j(0)].$$

• LFC:
$$\tau_i^{\text{LFC}} = \log(\mathbb{E}[Y_i(1)]/\mathbb{E}[Y_i(0)]).$$

Here, we use Y_j to denote the random variable of the *j*th outcome and $(Y_j(0), Y_j(1))$ to denote its potential outcomes. Next, we present the corresponding influence functions under the identification assumptions, Assumptions 1–3. Before we present the influence functions, we introduce the uncentered influence function for $\mathbb{E}[Y_j(a)]$ and $\mathbb{E}[Y_j(0)^2]$:

$$\phi_{-ja}(O;\pi_a,\mu_{ja}) = \frac{\mathbb{1}\{A=a\}}{\pi_a(W)}(Y_j - \mu_{ja}(W)) + \mu_{ja}(W), \qquad a = 0,1$$

$$\phi_{j2}(O;\pi_0,\mu_{j2}) = \frac{\mathbb{1}\{A=0\}}{\pi_0(W)}(Y_j^2 - \mu_{j2}(W)) + \mu_{j2}(W),$$
¹²²¹

where $\mu_{ja}(W) = \mathbb{E}[Y_j \mid W, A = a]$ for a = 0, 1 and $\mu_{j2}(W) = \mathbb{E}[Y_j^2 \mid W, A = 0]$. Note that the (centered) influence function of $\mathbb{E}[Y(a)]$ is given by $\phi_{ja}(O; \pi_a, \mu_{ja}) - \mathbb{E}[Y_j(a)]$. It follows that

$$\eta_j^{\text{ATE}}(O;\pi,\mu_j) = \phi_{j1} - \phi_{j0} - \tau_j^{\text{ATE}}.$$

The efficient centered influence function of τ_i^{SATE} is given by

$$\eta_j^{\text{SATE}}(O; \pi, \mu_j) = \frac{\phi_{j1} - \phi_{j0}}{\sqrt{\mathbb{V}[Y_j(0)]}} - \tau_j^{\text{SATE}} \left[\frac{\phi_{j2} + \mathbb{E}[Y_j(0)^2] - 2\mathbb{E}[Y_j(0)]\phi_{j0}}{2\mathbb{V}[Y_j(0)]} \right].$$

See for example, Kennedy et al. (49, Equation (6)) and Du et al. (7, Equation (4.3)). Similarly, the efficient influence function τ_i^{FC} is given by

$$\eta_j^{\rm FC}(O;\pi,\mu_j) = \frac{\phi_{j1} - \phi_{j0}}{\mathbb{E}[Y_j(0)]} - \frac{\tau_j^{\rm FC}\phi_{j0}}{\mathbb{E}[Y_j(0)]}$$
¹²²⁹

$$\eta_j^{\text{LFC}}(O;\pi,\mu_j) = \frac{\phi_{j1}}{\mathbb{E}[Y_j(1)]} - \frac{\phi_{j0}}{\mathbb{E}[Y_j(0)]}.$$
¹²³⁰

In the current paper, we restrict our focus to LFC; however, our implementation also allows the computation and inference using other estimands listed above. When computing the LFCs, we use the size-normalized counts Y_{ij}/s_i adjusted by the size factors s_i in place of the raw count Y_{ij} . This is akin to taking a weighted average of the sample to estimate ATE (and, subsequently, LFC). Otherwise, the effect will be driven by cells with large library sizes.

CATE and VTE

Under standard identification assumptions of consistency, conditional exchangeability, and positivity as in Assumptions 1–3, the conditional average treatment effect (CATE) is identified by $\tau_j(w) = \mu_{j1}(w) - \mu_{j0}(w)$. This also applies to conditional log-fold change.

When one is only interested in the conditional effects in a subset of variable $S \subset [d_W + a]$, the DR-learner readily accommodates runtime confounding through the decomposition $\tau_S(w) = \mathbb{E}[\phi(O) | W_S = w_S]$. This decomposition implies that one may estimate $\tau_S(w)$ by regressing $\phi(O)$ on W_S , i.e. modifying the final regression step of the DR-learner.

Algorithm S2 Multiple testing on standardized treatment effects

- **Input:** The estimated influence function values $\hat{\eta}_{ij}$, the estimated variance $\hat{\sigma}_j^2$ for i = 1, ..., n and j = 1, ..., p. The FDP exceedance threshold c, the FDP exceedance probability α , and the number of bootstrap samples B. The threshold \tilde{c} to exclude genes with small variation.
- 1: Initialize the iteration number $\ell = 1$, the candidate set $\mathcal{A}_1 = \{j \in [p] \mid \widehat{\sigma}_i^2 \geq \widetilde{c}\}$, the set of discoveries $\mathcal{V}_1 = \emptyset$, and the maximal statistic of $M_1 = \max_{j \in \mathcal{A}_1} |t_j|$.
- 2: while not converge do
- Let $D_{n\ell} = \text{diag}((\widehat{\sigma}_j)_{j \in \mathcal{A}_\ell})$ be the diagonal matrix of the estimated standard deviations and $\widehat{\eta}_{i\ell} = (\widehat{\eta}_{ij})_{j \in \mathcal{A}_\ell}$ be the 3:
- vector of estimated influence function values at iteration ℓ . Draw multiplier bootstrap samples $\boldsymbol{g}_{\ell}^{(b)} = (\sqrt{n}\boldsymbol{D}_{n\ell})^{-1}\sum_{i=1}^{n} \varepsilon_{i\ell}^{(b)} \hat{\boldsymbol{\eta}}_{i\ell}$, where $\varepsilon_{i\ell}^{(b)}$'s are independent samples from $\mathcal{N}(0,1)$ for $i = 1, \dots, n$ and $b = 1, \dots, B$. 4:
- Compute the maximal statistic $M_{\ell} = \max_{j \in \mathcal{A}_{\ell}} |t_j|$. 5:
- Estimate the upper α -quantile of M_{ℓ} under $H_0^{(\ell)}$: $\tau_j^* = 0, \forall j \in \mathcal{A}_{\ell}$ by 6:

$$\widehat{q}_{\ell}(\alpha) = \inf\left\{ x \left| \frac{1}{B} \sum_{b=1}^{B} \mathbb{1}\{ \| \boldsymbol{g}_{\ell}^{(b)} \|_{\infty} \le x \} \ge 1 - \alpha \right\} \right.$$

- Set $j_{\ell} = \operatorname{argmax}_{j \in \mathcal{A}_{\ell}} |t_j|$ and $\mathcal{A}_{\ell+1} = \mathcal{A}_{\ell} \setminus \{j_{\ell}\}.$ 7:
- if $M_{\ell} > \widehat{q}_{\ell}(\alpha)$ then 8:
- Set $\mathcal{V}_{\ell+1} = \mathcal{V}_{\ell} \cup \{j_{\ell}\}.$ 9:
- 10: else
- Declare the standardized treatment effects in A_{ℓ} are not significant stop the step-down process. 11:
- end if 12:
- $\ell \leftarrow \ell + 1.$ 13:
- 14: end while

15: Augmentation: Set \mathcal{V} to be the union of \mathcal{V}_{ℓ} and the $||\mathcal{V}_{\ell}| \cdot c/(1-c)|$ elements from \mathcal{A}_{ℓ} with largest magnitudes of t_j . **Output:** The set of discoveries \mathcal{V} .

Supplementary Note S3: Data simulation and analysis

Bulk expression simulation details

The bulk expression data are generated using a Poisson distribution with a zero-inflation component. The setup involves generating a latent signal matrix influenced by random noise and specific parameters. The data generation process is described in Algorithm S3 in detail. For experimental results in Fig. 2, we set d = 2 and $r^* = 1$, and vary $n \in \{100, 200, 300\}$. For causarray, RUV, and RUV-III-NB, we provide the number of latent factors in $r \in \{2, 4, 6\}$. Because the simulated data consists of 3 cell types, which may be explained with 3 additional degrees of freedom, the best possible choice of the number of latent factors would be r = 4.

Algorithm S3 Data generation process for pseudo-bulk gene expressions.

- **Input:** Number of subjects *n*, number of covariates *d*, number of latent factors r_0 , number of cells per subject m = 10, number of genes p = 2000, number of significant genes s = 100, and zero-inflation probability $\psi = 0.1$.
- 1: (Signals) The *p*-dimensional signal is derived from multiplying the signal strength by a Beta distributed vector, modified by a random sign flip:

$$\beta_j \sim 0.5 \times \text{Beta}(1,0.1) \times (2 \times \text{Bernoulli}(0.5) - 1), \qquad j = 1, \dots, s_j$$

and $\beta_j \equiv 0$ for $j = s + 1, \dots, p$.

- 2: (Cell types) The 3 cell types are generated with means $\{-0.5, 0, 0.5\}$ and standard deviations drawn from Uniform(0.5, 1). For *n* subjects, the cell type assignment is randomly sampled from Categorical(3) and the cell-type specific means and scales are stored as *n*-dimensional vectors μ_{ct} and σ_{ct} .
- 3: (Covariates) Sample d observed covariates $W_{.j} \sim 0.5 \sigma_{ct} \times \mathcal{N}_n(\mu_{ct}, \mathbf{1}_n)$ for j = 1, ..., d, and unobserved covariates $W_{.j} \sim 0.25 \sigma_{ct} \times \mathcal{N}_n(\mu_{ct}, \mathbf{1}_n)$ for $j = d + 1, ..., d + r_0$.
- 4: (Treatments) Sample $\mathbf{A} \sim \text{Bernoulli}(\text{Logistic}(\mathbf{W}\boldsymbol{\alpha}))$ where $\boldsymbol{\alpha} \sim \mathcal{N}_d(\mathbf{0}_{d+r_0}, (4(d+r_0))^{-1/2}\mathbf{1}_{d+r_0})$.
- 5: (Coefficient matrix) Sample $b_{0j} \sim \text{Beta}(2,1)$ and $\mathbf{B}_{\cdot j} \sim \mathcal{N}_d(\mathbf{0}_{d+r_0}, (4(d+r_0))^{-1/2}\mathbf{1}_{d+r_0})$ for $j = 1, \dots, p$.
- 6: (Natural parameters) Let $\Theta = \mathbf{1} \mathbf{b}_0^\top + \mathbf{W} \mathbf{B}^\top + \mathbf{A} \boldsymbol{\beta}^\top$.
- 7: (Single-cell observations) Let $\mathbf{Y}^{sc} \in \mathbb{R}^{n \times p \times m}$ with $\mathbf{Y}^{sc}_{\dots \ell} \sim \text{Bernoulli}((1 \psi) \times \mathbf{1}_{n \times p}) \times \text{Poisson}(\exp(\Theta))$ for $\ell = 1, \dots, m$.
- 8: (Bulk observations) Let $Y \in \mathbb{R}^{n \times p}$ with $Y = \sum_{\ell=1}^{m} Y_{\cdot \cdot \ell}^{\text{sc}}$.
- **Output:** Covariates W, treatment A, single-cell gene expression Y^{sc} , and bulk gene expression Y.

Single-cell expression simulation details

The single-cell expression data are generated by Splatter (25). Splatter explicitly models the hierarchical Gamma-Poisson pro-1253 cesses that give rise to data observed in scRNA-seq experiments and can model the multiple-faceted variability. The data is 1254 generated from splatSimulate function from Splatter (1.26.0) package (25). When calling this function, the treatment ef-1255 fects are simulated with the parameters: group.prob = c(0.5, 0.5), method = "groups", de.prob=0.05, 1256 de.facLoc=1., de.facScale=0.5, de.downProb=0.5; the dropout effects are simulated with the parameters: 1257 dropout.type="experiment", dropout.mid=20, dropout.shape=0.001; the batch effects are simulated 1258 with the parameters: batch.facLoc=noise, batch.facScale=0.5; while all the other parameters are the same as 1259 returned by the function newSplatParams. For experimental results in Fig. S1, we generate d = 1 covariates and r = 41260 unmeasured confounders. We first generate (d+r+1)/2 batches with equal sample sizes, which account for d+r degrees of 1261 freedom. To simulate varying confounding levels, we set noise in $\{0.1, 0.2, 0.3\}$. 1262
